ELCOMP Publishing, Inc., 53 Redrock Lane, Pomona CA 91766

PREFACE

Since more and more users of the ATARI personal computers write programs in machine language, more and more "workhorse"-routines, performing standard tasks, are required.

This book contains a variety of programs for the real computer "Hacker" and the machine language programmer.
All the programs have been fully tested and a complete source code is provided.
I extend my thanks to Franz Ende for the translation and Karl Wagner for his proofreading.

Munich, Spring 1983 H. C. Wagner

IMPORTANT NOTICE

This book is written for the experienced ATARI Personal Computer owner. To run the programs you need a symbolic Editor/Assembler or the ATAS/ATMAS from ELCOMP Publishing. For details please refer to the OS-Manual from ATARI.

CHAPTER 1

1-1 Input and output of numbers

When working with numbers one often wants to input and output them via the screen. The following programs show how this can be done with hexadecimal as well as decimal numbers.

1-1-1 Hexadecimal input

This program allows you to enter hexadecimal numbers using the keyboard. The number entered is displayed on the screen. The input stops if a character different from the hexadecimal numbers (0.. F) is entered.
The program first deletes memory locations EXPR and EXPR+1. This ensures a result equal to zero, even if an invalid number is entered. Next, the program reads a character and checks whether or not it is a hexadecimal number. If it is, then the upper bits of the number in the accumulator are erased and the lower bits are shifted up. Now, these four bits can be shifted to EXPR from the right. The preceeding number in EXPR is shifted to the left by doing so.
If you enter a number with more than four digits, only the last four digits are used.

Example : ABCDEF => CDEF

1-1-2 Hexadecimal output

The next program explains the output process of the calculated numerals.
You will recognize, that the portion of the program which controls the output is a subroutine. This subroutine only displays the contents of the accumulator. This means that you first have to load the accumulator with, for example, the contents of EXPR+1, then jump into the subroutine where first the MSB (EXPR+1 in our case) and then the LSB (EXPR) will be printed.
Subroutine PRBYTE independently prints the most significant bytes of the accumulator first and the least significant bytes second.

1-1-3 Decimal input

When you calculate with numbers you probably prefer decimals over hexadecimals. The following program can be used to read decimal numbers and convert them into binary numbers readable by computers.
The program first checks, to see if the input is a decimal number (0..9) or if the input has been terminated by another character. EXPR and EXPR+1 are erased. If a digit is accepted then the upper bits are erased. Next the contents of EXPR and EXPR+1 are multiplied by 10 and the new number is added. In the end the MSB is in location EXPR+1 and the LSB is in location EXPR.
Numbers greater than 65535 are displayed in modulo 65536 (the rest which remains after deduction of 65535).

1-1-4 Decimal output

The next program allows you to display decimal numbers.
The program works as follows :
The X-register is loaded with the ASCII equivalent of the digit 0. This number is then incremented to the highest potency of 10 (10000) and is displayed on the screen.

The same procedure is repeated for 1000, 100, and 10. The remaining is converted into an ASCII number, using an OR-command, and is displayed.
You might want to change the output routine so that it avoids leading zeroes.

1-2-3 16-bit multiplication

The multiplication is much more complicated than addition or subtraction. Multiplication in the binary number system is actually the same as in the decimal system. Let's have a look at how we multiply using the decimal system. For example, how do we calculate 5678*203 ?

```
       5678
        203 *
       ------

      17034
     00000
    11356
    --------

    1152634
```

With each digit the previous number is shifted to the right. If the digit is different from zero the new interim results are added. In the binary system it works the same way. For example :

```
        1011
        1101 *
        ----

        1011
       0000
      1011
     1011
     -------

    10001111
```

As you can see it is simpler in the binary system than in the decimal system. Since the highest possible number for each digit is 1 the highest interim results is equal to the multiplicand.
The following program in principle does the same as the procedure described above, except that the interim result is shifted to the right and the multiplicand is added, if required. The results are the same.
Six memory locations are required. Two of these (SCRATCH and SCRATCH+1) are used only part of the time, while the other

four locations keep the two numbers to be multiplied (EXPR1 and EXPR1+1, EXPR2 and EXPR2+1). After the calculations the result is in locations EXPR1 (LSB) and EXPR1+1 (MSB).

```
     *************************************
     *                                   *
     *        16 BIT MULTIPLICATION      *
     *                                   *
     *        UNSIGNED INTEGER           *

1-2-4 16-bit division

The division of two numbers actually is just the opposit of the multiplication. Therefor, you can see in the program below, that the divisor is subtracted and the dividend is shifted to the left rather than to the right. The memory locations used are the same as with the multiplication, except that locations SCRATCH and SCRATCH+1 are named REMAIN and REMAIN+1. This means the remainder of the division is stored in those locations.

STRINGOUTPUT

CHAPTER 2

2-1 Output of text

With most programs it is necessary to display text (menues etc.).
The following program allows you to display strings of any length at any location you desire. The output command can be located at any place within your program.
How does that program work ?
As you know the 6502 microprocessor uses its stack to store the return address if a JSR-command is to be executed. The number that is stored on the stack actually is the return-address minus one. The trick used in this program is, that the string to be printed is stored immediately after the JSR-command and the last character of the string is incremented by 128. The subroutine calculates the start address of the string, using the number on the stack, and reads the string byte by byte, until it finds the byte which has been incremented by 128. The address of this byte now is stored on the stack and an RTS-command is executed. By doing so, the string is jumped and the command after it is executed.

```

INTRODUCTION TO CIO

CHAPTER 3

The CIO can handle up to 8 devices/files at the same time. This happens via so called IO-ControlBlocks (IOCB). This means that there are 8 IOCB'S starting from $0340. Each of the IOCB's is 16 bytes long.

```
+-----------------+
¶     IOCB #0     ¶ $0340
+-----------------+
¶     IOCB #1     ¶ $0350
+-----------------+
¶     IOCB #2     ¶ $0360
+-----------------+
¶     IOCB #3     ¶ $0370
+-----------------+
¶     IOCB #4     ¶ $0380
+-----------------+
¶     IOCB #5     ¶ $0390
+-----------------+
¶     IOCB #6     ¶ $03A0
+-----------------+
¶     IOCB #7     ¶ $03B0
+-----------------+
```

A single IOCB has the following internal scheme:

```
+-----------------+
¶      ICHID      ¶ HANDLER ID
+-----------------+
¶      ICDNO      ¶ DEVICE NUMBER
+-----------------+
¶      ICCMD      ¶ COMMAND
+-----------------+
```

```
¶      ICSTA       ¶ STATUS
+-----------------+
¶      ICBAL       ¶
+-               -+ BUFFERADR
¶      ICBAH       ¶
+-----------------+
¶      ICPTL       ¶
+-               -+ PUTADR
¶      ICPTH       ¶
+-----------------+
¶      ICBLL       ¶
+-               -+ BUFFERLEN
¶      ICBLH       ¶
+-----------------+
¶      ICAX1       ¶ AUX1
+-----------------+
¶      ICAX2       ¶ AUX2
+-----------------+
¶      ICAX3       ¶ Remaining 4 byte
+-----------------+
¶      ICAX4       ¶
+-----------------+
¶      ICAX5       ¶
+-----------------+
¶      ICAX6       ¶
+-----------------+
```

There are just a few locations which are important to the user:

- The commandbyte which contains the command to be executed by the CIO.
- The bufferaddress which contains the address of the actual databuffer.
- The bufferlength which contains the number of bytes to be transferred (rounded up to a variety of 128 bytes for the cassette device)
- And there are two auxiliaries which contain device-dependent information.

There are also locations which will be altered by CIO such as:

- The handler-ID is an offset to the devicetable. This table contains all devicenames and pointers to the device-specific handlertable.

```
+----------------+  --+
¶  device name   ¶    ¶
+----------------+    ¶
¶  handler table ¶    +-- one entry
+-              -+    ¶
¶     address    ¶    ¶
+----------------+  --+
¶     other      ¶
*                *
¶     entries    ¶
+----------------+
¶  zero fill to  ¶
*                *
¶  end of table  ¶
+----------------+
```

A handlertable looks like:

```
+----------------+
¶     OPEN-1     ¶
+----------------+
¶     CLOSE-1    ¶
+----------------+
¶    GETBYTE-1   ¶
+----------------+
¶    PUTBYTE-1   ¶
+----------------+
¶   GETSTATUS-1  ¶
+----------------+
¶    SPECIAL-1   ¶
+----------------+
¶    JMP INIT    ¶
¶     & 00       ¶
+----------------+
```

The CIO is thus quite clear to the user. It is easy to add new devices by adding just 3 bytes to the devicetable and to make a specific handlertable for this device. You can also change the handlerpointer of an existing device and let point it to a new handler. Later we will describe how to add or change devices.

- The devicenumber shows us which subdevice is meant. (e.g. Disknumber or RS232 Channel).
- After calling CIO the status will be altered. A 1 means a successfull operation while a value greater than 128 means an error has occurred.
- PUTADR is used internally by the CIO
- If there have been less bytes transferred than desired, because of an EOL or an error, BUFLEN will contain the actual number of transferred bytes.

The standard CIO commands:

- OPEN opens a file.

Before execution the following IOCB locations have to be set:
COMMAND = $03
BUFFADR points to device/filename specification (like C: or D: TEST. SRC) terminated by an EOL ($9B)
AUX1 = OPEN-directionbits (read or write) plus devicedependent information.
AUX2 = devicedependent information.

After execution:
HANDLER ID = Index to the devicetable.
DEVICE NUMBER = number taken from device/filename specification
STATUS = result of OPEN-Operation.

- CLOSE closes an open IOCB

Before execution the following IOCB location has to be set:
COMMAND = $0C

After execution:
HANDLER ID = $FF
STATUS = result of CLOSE-operation

- GET CHARACTERS read byte aligned. EOL has no termination feature.

Before execution the following IOCB locations have to be set:
COMMAND = $07
BUFFERADR = points to databuffer.
BUFFERLEN = contains number of characters to be read. If BUFFERLEN is equal to zero the 6502 A-register contains the data.

After execution:
STATUS = result of GET CHARACTER-operation
BUFFERLEN = number of bytes read to the buffer. The value will always be equal before execution, only if EOF or an error occurred.

- PUT CHARACTERS write byte aligned

Before execution the following IOCB locations have to be set:
COMMAND = $0B
BUFFERADR = points to the databuffer
BUFFERLEN = number of bytes to be put, if equal to zero the 6502 A-register has to contain the data.

After execution:
STATUS = result of PUT CHARACTER-operation

- GET RECORD characters are read to the databuffer until the buffer is full, or an EOL is read from the device/file.

Before execution the following IOCB locations have to be set:
COMMAND = $05
BUFFERADR = points to the databuffer
BUFFERLEN = maximum of bytes to be read (Including EOL character)

After execution:
STATUS = result of the GET RECORD-operation
BUFFERLEN = number of bytes read to buffer this may less then the maximum length.

- PUT RECORD characters are written to the device/file from the databuffer until the buffer is empty or an EOL is written. If the buffer is empty CIO will automatically send an EOL to the device/file.

Before execution the following IOCB locations have to be set:
COMMAND = $09
BUFFERADR = points to databuffer
BUFFERLEN = maximum number of bytes in databuffer.

After execution:
STATUS = result of PUT RECORD-operation.

In addition to the main-commands, there is also a GET STATUS ($0D) command, which obtains the status from the device/file-controller and places these four bytes from location $02EA (DVSTAT). Commands greater than $0D are so called SPECIALS and devicehandler-dependent.

GET STATUS and SPECIALS have an implied OPEN-option. Thus the file will be automatically opened and closed if it wasn't already opened.

How to link the CIO with machine language?

First we have to modify the IOCB before calling CIO.

The offset to the IOCB (IOCB# times 16) has to be in the X-register. The STATUS will be loaded in the Y-register after returning from CIO. It is not necessary to explicitly check the Y-register (Comparing with 128) because loading the status into the Y-register was the last instruction before leaving CIO with an RTS. We simply jump on the signflag (BMI or BPL). The signflag is set if an error occurred. In the next section we will discuss it in more detail with an example.

How to read or write data

in machine-language

To describe the writing of data to a device/file we will take the cassette-device as an example. We can also use any other device because CIO is very clear-cut (see introduction).

Before discussing the program, some conventions must be discussed.

The user has to put the address of his databuffer into the locations BUFFER ($80.

1) and the bufferlength into the locations BUFLEN ($82.3). Then the program should be called as a subroutine. The description of this subroutine follows.

First we have to open the cassette, so we load the IOCB-offset in the X-register, store the OPEN-command in ICCMD, and let the BUFADR (ICBAL and ICBAH) point to the device/filename specification. We have to store the write-direction in ICAX1 and the tape-recordlength (128) in ICAX2, just call CIO ($E456). The Signflag indicates if an error occurred.

After a correct opening of the file for writing data, bit 3 is set because AUX1 contains a $08 (bit 2 is readbit).

```
+---------------+
¶ ¶ ¶ ¶ ¶W¶R¶ ¶ ¶   AUX1
+---------------+
 7 6 5 4 3 2 1 0
```

ICCMD will be changed into the PUT CHARACTERS-command ($0B), BUFADR points to the User-Databuffer (contents of BUFFER) and BUFLEN (ICBLL and ICBLH) will contain the number of bytes to write (the user stores this value BUFLEN ($82. 3)). Next CIO will be called, and after successfull operation, the file will be closed (ICCMD=$0C).

If, during any of these three CIO-calls, an error occurs, the file will be closed and both the ACCUMULATOR and Y-register will contain the STATUS (errorcode).

By changing the string at CFILE in for instance 'D: TEST. TST' the program will write the buffer to the specified diskfile.

The second listing shows you a program that reads from a device, only two bytes are different, so the program is self-explaining.

INTRODUCTION TO THE DISK-CONTROLLER

CHAPTER 4

We already know how to handle any device/file via CIO, including handle a diskfile. Included on a disk is also a a sector-IO which allows you to address a single sector for a read- or write-handling. Sector-IO doesn't need any file on the disk. The disk has only to be formatted.
A floppy disk with the ATARI-drive has 720 sectors and each of them is fully addressable.
How does the sector-IO function?
The disk-controller has a simplistic design containing a single IOCB like Data Control Block (DCB). This DCB is described in the following scheme.

```
+-----------------+
¶     DCBSBI      ¶ Serial bus ID
+-----------------+
¶     DCBDRV      ¶ Disk drive #
+-----------------+
¶     DCBCMD      ¶ Command
+-----------------+
¶     DCBSTA      ¶ IO Status
+-----------------+
¶     DCBBUF   LO ¶
+-               -+ IO Buffer address
¶     DCBBUF   HI ¶
+-----------------+
¶     DCBTO    LO ¶
+-               -+ Time out count
¶     DCBTO    HI ¶
+-----------------+
```

```
¶      DCBCNT  LO ¶
+-               -+ IO Buffer length
¶      DCBCNT  HI ¶
+-----------------+
¶      DCBSEC  LO ¶
+-               -+ IO Sector number
¶      DCBSEC  HI ¶
+-----------------+
```

- Instead of a handler-ID there is a BUS-ID (DCBSBI) to address a particular diskdrive via the Serial-Bus of the ATARI.
- Also a logical drivenumber (DCBDRV)
- A commandbyte (DCBCMD), which is similar to an IOCB, and 5 commands for sector-IO, which will be described later.
- The statusbyte for error detection after, and data-direction previous to execution of the command ($80 is write, $40 is read).
- The DCBBUF locations (L and H) to point to the databuffer.
- DCBTO (L & H) is a special word containing the maximum time for executing a command, so called timeout.
- DCBCNT (L & H) is a device specific word which contains the sector length (128 for the 810-drive or 256 for the double density drives).
- DCBSEC (L & H) contains the sector number to do IO on.

The DCB-commands

Prior to executing any DCB-command, the following DCB-entries must be set.
DCBSBI has to contain the bus-ID of the drive:

```
DRIVE 1 = $31 = '1
DRIVE 2 = $32 = '2
DRIVE 3 = $33 = '3
DRIVE 4 = $34 = '4
```

DCBDRV has to contain the logical drive number (1..4).
DCBTO the timeout (normally 15 lowbyte=$0F highbyte=$00).

- READ SECTOR reads one sector specified by the user

DCBCMD = $52 = 'R
DCBBUF = points to databuffer
DCBCNT = contains sector length
DCBSEC = number of sector to read

After execution:
DCBSTAT = result of READ SECTOR-operation

- PUT SECTOR writes one sector specified by the user without verify.

DCBCMD = $50 = 'P
DCBBUF = points to databuffer
DCBSEC = number of sector to write

After execution:
DCBSTAT = result of PUT SECTOR-operation

- WRITE SECTOR writes one sector specified by the user with automatic verify.

DCBCMD = $57 = 'W
Further like PUT SECTOR.

- STATUS REQUEST obtains the status from the specified drive.

DCBCMD = $53 = 'S

After execution:
DCBSTAT = result of STATUS REQUEST-operation
The drive outputs four bytes and the controller puts them to $02EA (DVSTAT).

- FORMAT formats the specified disk.

DCBCMD = $21 = '!
DCBTO = has to be larger than 15 due to more time taken by the FORMAT-command. You can ignore the error, but this will be risky.

After execution:
DCBSTAT = result of the FORMAT-operation.

How is the disk controller invoked?
Because the disk controller is resident, this is a simple process. You don't have to load DOS, nor anything similar. You just have to call the SIO (Serial IO $E459) instead of the CIO. Therefore, you can see that it is quite easy to link the Diskcontroller with machine language.

How to write a sector to disk

The first program writes a specified sector from a buffer to diskdrive# 1. There are a few conventions to call this program as subroutine. The user has to put the buffer address into the pointer locations labelled BUFFER and the sector number into the locations labelled SECTR. The program also needs a RETRY-location, to serve as a counter so the program is able to determine how often it will retry the IO.

The next paragraph describes the subroutine.

At first we built the DCB, special we move a $80 (BIT 3 the write bit is set) to DCBSTA and we retry the IO 4 times. SIO does, as well as CIO, load the STATUS into the Y-register so you only have to check the signflag again. After an error occurence we decrement the retry value and set DCBSTA again, then try again.

By using this program, you only have to look at the signflag after returning for error detection (signflag TRUE means error, otherwise success).

The second program reads a sector instead of writing it. The only two bytes which are different are the DCBCMD and the DCBSTA ($40 for read).

HOW TO MAKE A BOOTABLE PROGRAM

CHAPTER 5

What is a bootable program ?
A bootable program is a program which will be automatically loaded at powering up the ATARI, and directly after loading be executed.
A bootable program needs a header with specific information about the program, such as the length and the start address.
The header of a bootable program looks like the following scheme :

```
+----------------+
¶     unused     ¶  first byte
+----------------+
¶ # of 128 bytes ¶
+----------------+
¶      store     ¶
+-              -+
¶     address    ¶
+----------------+
¶ initialization ¶
+-              -+
¶     address    ¶  sixth byte
+----------------+
¶      boot      ¶
¶  continuation  ¶
¶      code      ¶
```

- The first byte is unused, and should equal zero.
- The second byte contains the length of the program, in records (128 bytes), (rounded up).
- The next word contains the store-

address of the program.
- The last word contains the initialization-address of the program. This vector will be transferred to the CASINI-vector ($02.3).

After these 6 bytes there has to be the boot continuation code. This is a short program, the OS will jump to directly after loading. This program can continue the boot process (multistage boot) or stop the cassette by the following sequence :

```
LDA #$3C
STA PACTL ;$D302
```

The program then allows the DOSVEC ($0A. B) to point to the start address of the program. It is also possible, to store in MEMLO ($02E7. 8), the first unused memory address. The continuation code must return to the OS with C=0 (Carry clear). Now OS jumps via DOSVEC to the application-program.
So far we know what a bootable cassette looks like, but how do we create such a bootable tape?

If there is a program, we only have to put the header in front of it (including the continuation code) and to save it as normal data on the tape. We can use the later described program to write the contents of a buffer on the tape or the boot generator.
If the program is saved, we can put the tape in the recorder, press the yellow START-key, power on the ATARI and press RETURN. Now the program on the tape will be booted.
The next listing shows us the general outline of a bootable program.

```

How to make a bootable disk

Making a bootable disk is in fact the same as for the cassette. The only exceptions are as follows.
The program (including the header) must be stored up from sector one. The boot continuation code doesn't need to switch off anything such as the cassette motor.
How to create a bootable disk ?
This is only a bit more complicated than the cassette version. We need our write-sector program we described earlier. Then we have to write, sector by sector, to disk. You can also make a bootable cassette first and then copy it directly to disk with the later discussed program.

HOW TO MAKE A BOOTABLE CARTRIDGE

CHAPTER 6

Preparing the program.

Most of the games and some other programs written in machine language are stored in a cartridge. Booting a program, the OS recognizes the cartridge and starts the program.
What do you have to do when you want to make a bootable cartridge of your own program ?
As an example we will make a cartridge with a program for testing the memory. The bit pattern

```
10101010 = $AA
01010101 = $55
00000000 = $00
11111111 = $FF
```

is written in every memory location starting above the hardware stack at address $200. First the content is saved, then the bit pattern is written into and read from the memory location. If there is any difference in writing and reading the program prints an error message : ERROR IN <ADR> . Then the program waits in an endless loop. If the error message is ERROR IN A000, the RAM is ok because $A000 is the first address of the ROM in the left cartridge.

The address range for the left cartridge ranges from $A000 to $BFFF and $8000 to $9FFF for the right cartridge. As starting address for our memory test program we choose $BF00. This is the last page of the left cartridge. The software for the EPROM burner is also stored in a cartridge. Therefore the object code generated by the assembler is stored at $9000.

Like a bootable program the cartridge has a header. The following scheme shows the outline of this cartridge header.

```
+-----------------+   $BFFA or
|   cartridge     |   $9FFA
+-               -+
| start address   |
+-----------------+
|       00        |
+-----------------+
|  option byte    |
+-----------------+
|   cartridge     |
+-               -+
|  init address   |   $BFFF or
+-----------------+   $9FFF
```

The header for the right cartridge starts at $9FFA, for the left cartridge (the more important for us) at $BFFA.

- The first two bytes contain the start address of the cartridge.
- The third byte is the cartridge-ID. It shows the OS that a cartridge has been inserted. It must be 00.
- The fourth byte is the option-byte. This byte has the following options:

```
BIT-0 = 0 don't allow diskboot
        1 allow diskboot
BIT 2 = 0 only initialize the
          cartridge
        1 initialize and start
          the cartridge
```

```
BIT 7 = 0 Cartridge is not a diagnostic
            cartridge
        1 Cartridge is a diagnostic
            cartridge
          before OS is initialized
          the cartridge takes control
```

- The last two bytes contain the cartridge initialization address.
The initialization address is the starting address of a program part which is executed in advance of the main program. If there is no such a program this address must be the address of an RTS instruction. In our example the low byte of the starting address $BF00 is stored in location $BFFA, the high byte in location $BFFB.
The option byte in location $BFFD is 04.

The program in the cartridge is initialized and started, but there is no disk boot. The initializing address is $BF63, an RTS instruction within the program.

After assembling and storing the object code the burning of an EPROM can start.

```

EPROM-BURNER FOR THE ATARI 800/400®

With this epromburner you can burn your own EPROMS.It is possible to burn four different types. The four types are the 2532(4k), the 2732(4k),the 2516(2k) and the 2716(2k). The burner uses the game ports 1 ,2 and 3.

1) THE HARDWARE.

The circuit of the epromburner is shown in FIG. 1.The data for the burner is exchanged via game port 1 and 2. The control signals are provided by game port 3.The addresses are decoded by two 7 bit counters 4024. The physical addresses for the EPROMS are always in the range of 0000 to 07FF for 2k and 0000 to 0FFF for 4k. This counter is reset by a signal, decoded from PB0 and PB1 via the 74LS139. PB2 is used to decide if a 2532, or a 2716 has to be burned.
Not all signals for the different types of EPROMS are switched by software.A three pole, double throw switch is used to switch between the different types.The software tells you when you have to set the switch into the correct position. For burning, you need a burning voltage of 25 Volts.This voltage is converted from the 5 Volts of the game port to 28 Volt by the DCDC converter DCP 528. This voltage is limited to 25 Volts by two Zener diodes in serie (ZN 24 and ZN 1). Three universal NPN transistors are used to switch between low level voltages and the high level of the burning voltage.

2) ASSEMBLING THE BURNER.

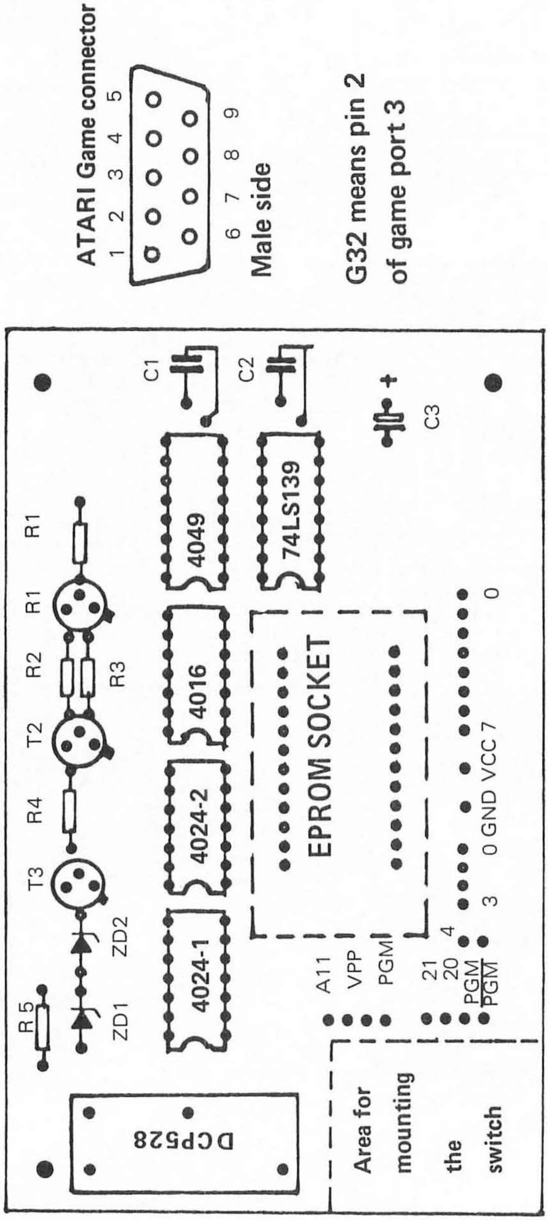

Fig. 2: Parts Layout

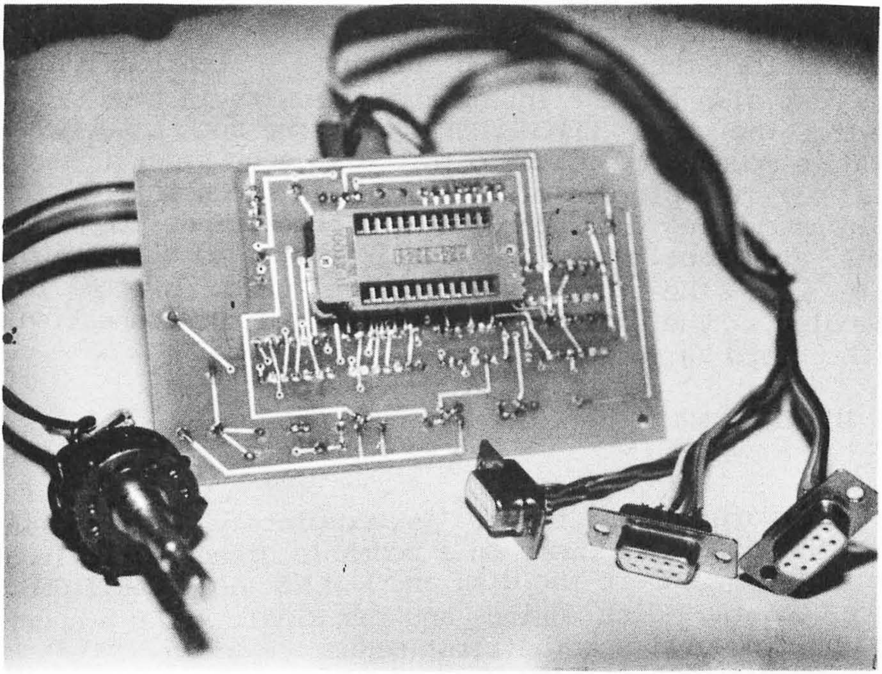

Figure 3

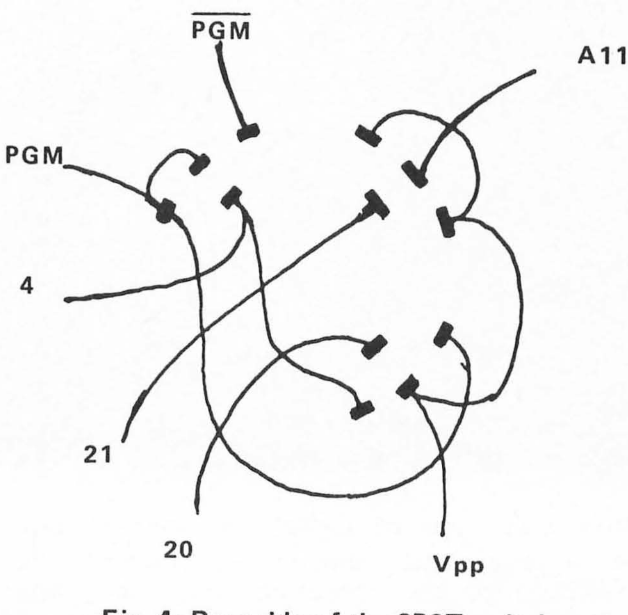

Fig. 4: Rear side of the 3P2T switch

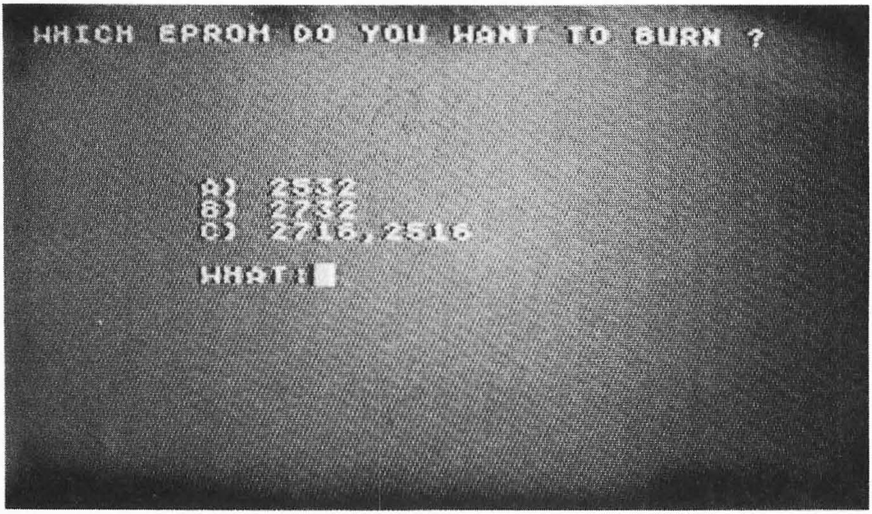
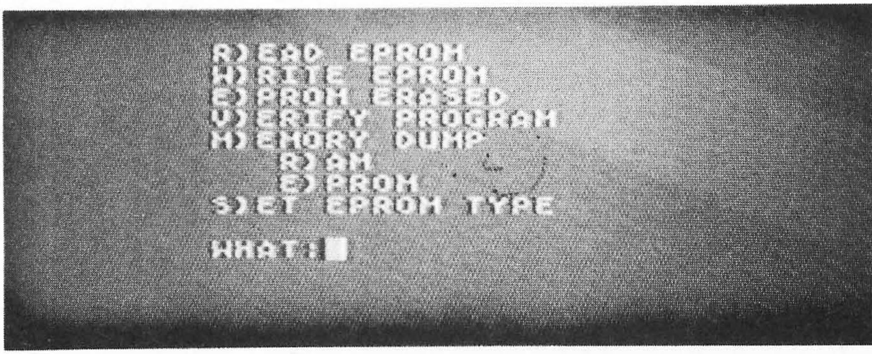
FIG.2 shows the parts layout.It is recomended to use sockets for the integrated circuits. Attention !.The component side for the integrated circuits is the side showing the text EPROMBURNER, but the socket for the EPROM is mounted opposite to this component side. (see FIG. 3) The picture of the burner is shown in FIG. 3. After assembling the board, the connections to the ATARI are made. Use three female plugs and a flatband cable. Last the three pole double throw switch is assembled. The wiring of the switch and the connection to the board is shown in FIG.4.

3) THE SOFTWARE

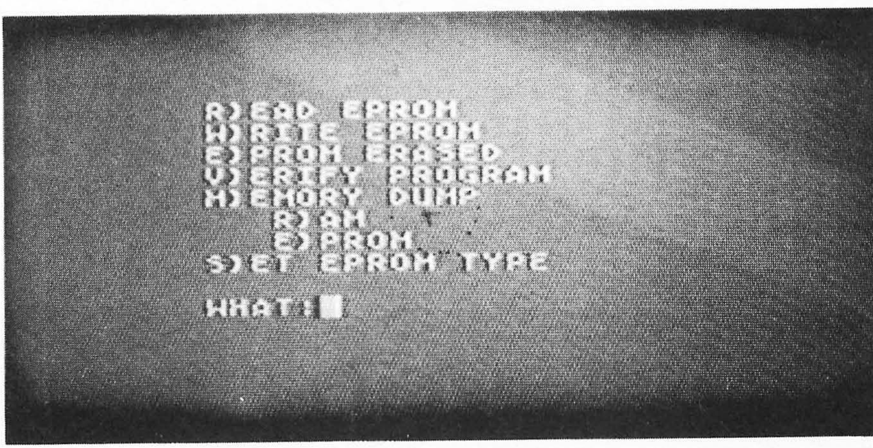
The software for the burner is completely written in machine code. It comes on a bootable diskette. To load the program, insert the disk and REMOVE ALL CARTIDGES. Turn on the disk drive and the ATARI. After a short moment, you will see the first menue:



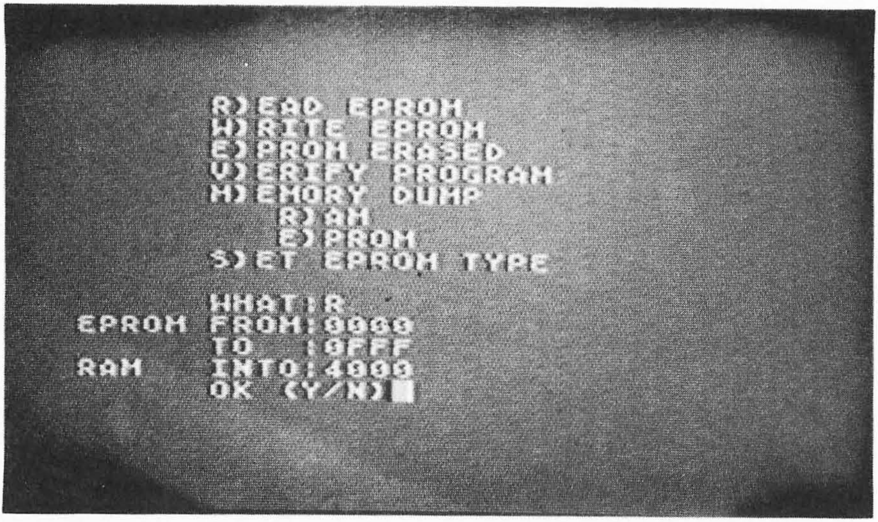
You are asked what type of EPROM you want to burn. After typing the appropriate character, you get the message to set the switch to the correct position and insert the EPROM. This is shown in the following example:



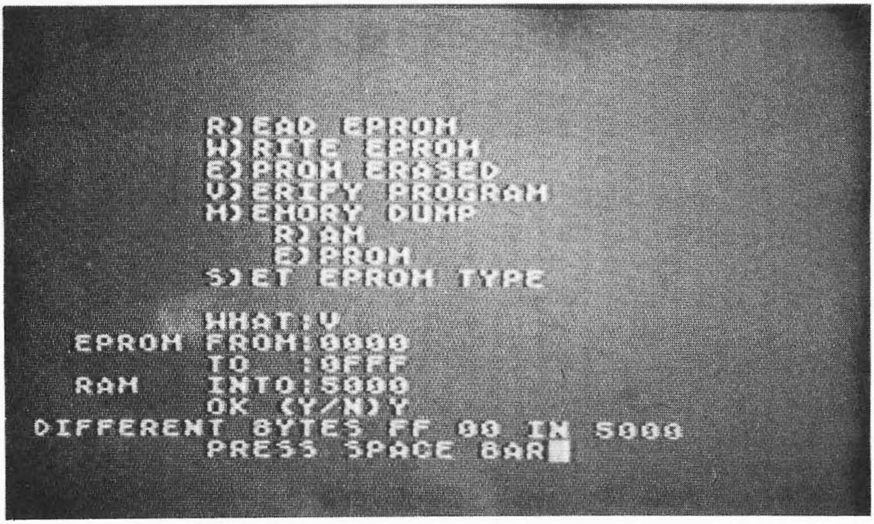
Then, pressing the space bar, you see the main menue:



First we want to R)EAD an EPROM. Type R and then the addresses FROM and TO. The physical addresses of the EPROM are always in range between 0000 and 0FFF. You can read the whole EPROM or only a part of it. Next you have to type the address INTO which the content of the EPROM is read. All adresses which are not used by the system or the burner software (A800 to AFFF) are accessible. By typing Y after the question OK (Y/N), the program is loaded. There is a very important key, the X key. This key cancels the input and leads back into the main menue. An example of reading an EPROM is shown in the next figure:



To verify that the content of the RAM is idetical to the content of the EPROM, type V. After specifing the adresses for the EPROM and the RAM and typing Y, the contents are compared. If there are any differences, you get an error message, such as the following:



You may then make a memory dump. Type M for M)EMORY, either R for R)AM or E for E)PROM, and the address range. There is a slight difference in memory dumps. With the memory dump of RAM, the bytes are printed, if it is possible, as ASCII characters.

Burning an EPROM begins by testing as to whether or not the EPROM is erased in the address range you want to burn. Type E and the address range. You will get the message EPROM ERASED when the assigned address range has been erased, or the message EPROM NOT ERASED IN CELL NNN.
For writing the EPROM, type W, the address range in RAM, and the starting address in EPROM. After hitting Y, you have to wait two minutes for burning 2k and four minutes for burning 4k.Don't get angry, the program will stop. After burning one cell the program does an automatic verify. If there is a difference you recieve the error message EPROM NOT PROGRAMMED IN CELL NNN and the burning stops. Otherwise if all goes well the message EPROM PROGRAMMED is printed.
For changing the type of EPROM you want to burn, type S. The first menue is shown and you can begin a new burning procedure.

4) PARTS LIST.

IC1	74LS139	
IC2,IC3	4024	
IC4	4016	
IC5	4049	
T1,T2,T3	UNIVERSAL NPN TRANSISTOR 30V,0.3W (2N 3390 % 2N3399)	
R1	470 K	RESISTOR
R2,R3	100 K	RESISTOR
R4,R5	33 K	RESISTOR
Z1	1 V	ZENER DIODE
Z2	24 V	ZENER DIODE
M1	DCP528	DCDC CONVERTER ELPAC POWER SYSTEMS
C1,C2	100 NF	CAPACITOR

C3	10 MF	TANTAL CAPACITOR
S1	3P2T	SWITCH
1	24 PIN	TEXTOOL SOCKET
3	14 PIN	IC SOCKET
2	16 PIN	IC SOCKET
3	FEMALE PLUGS, ATARI GAME CONNECTORS	

5) STEP BY STEP ASSEMBLING.

1. Insert and solder sockets.
* Component side shows the text EPROMBURNER.
2. Insert and solder resistors.
3. Insert and solder Zener diodes.
* The anodeS are closest to the to the
* transistors.
4. Insert and solder transistors.
5. Insert and solder capacitors.
* The + pole of the tantal is marked.
6. Mount the DCDC converter module.
7. Turn the board to the soldering side.
8. Insert from this side the TEXTOOL socket.
* The knob should be in the
* upper right corner. Solder the socket.
9. Make the connections on the switch. (FIG.4)
* Connect switch and board via
* a 7 lead flatband cable.
10. Connect the plugs to the board. (FIG.5)
11. Insert the integrated circuits.(FIG.2)
12. Turn off the ATARI. Insert the plugs.
* Insert the diskette and turn on the ATARI.

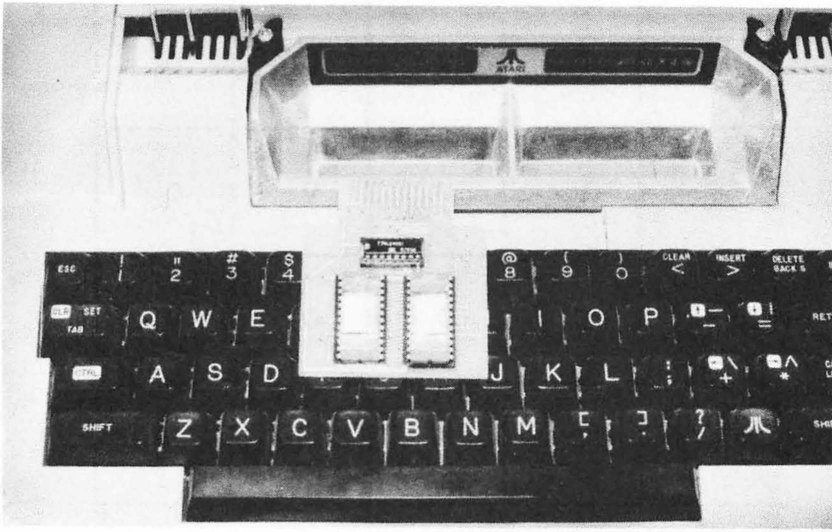
This hexdump has to be keyed in starting at address A800. This means you need a 48K RAM ATARI and a machine language monitor (ATMONA-1, Editor/Assembler cartridge from ATARI or ATMAS-1). The program starts at address A800 hex.

Using the EPROM board Kit from HOFACKER

After you burned an EPROM you certainly want to plug it into your ATARI. For this you need a pc-board. You can buy those boards from various vendors (APEX, ELCOMP PUBLISHING).

The following description shows how to use the EPROM board from ELCOMP PUBLISHING, INC.



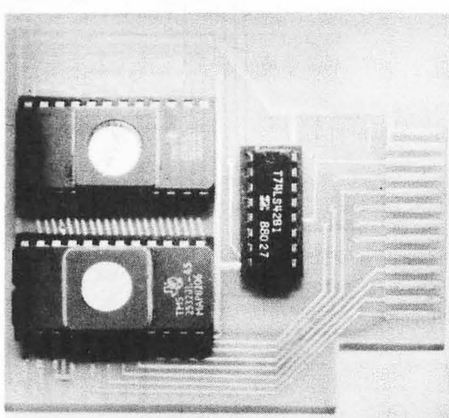
With this versatile ROM module you can use

2716
2732
and 2532 type EPROMs.

To set the board for the specific EPROM, just solder their jumpers according to the list shown below. Without any soldering you can use the module for the 2532 right away.

If you use only one EPROM, insert it into the right socket. If you use two EPROMs, put the one with the higher address into the right socket.

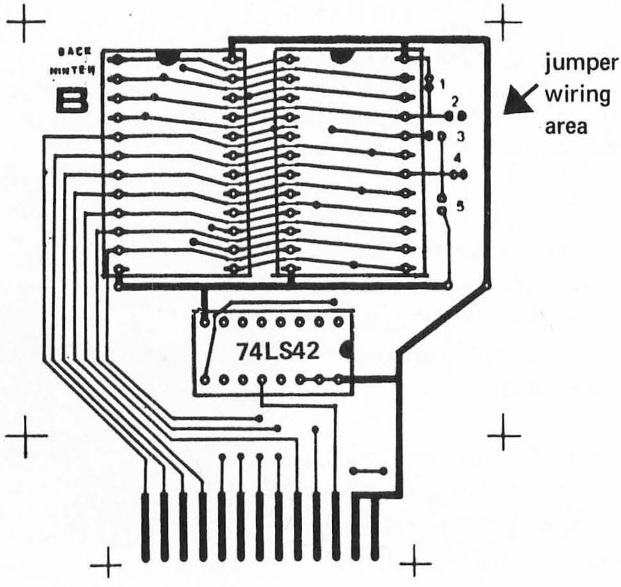
The modul must be plugged into the left slot of your ATARI computer with the parts directed to the back of the computer.



EPROM	2716	2732	2516	2532
1	V	0	V	V
2	0	V	0	0
3	V	V	V	0
4	0	0	0	V
5	0	V	0	0

V = means connected (jumper)

0 = means open



HOW TO ADD OR CHANGE A DEVICE

CHAPTER 7

If you want to add your own device, you first have to write a handler/controller (interface). You have to submit the handler on the following design decisions.

- There has to be an OPEN routine, which opens the device/file and returns with the status of these operations stored in the Y-register of your 6502.

- You also need a CLOSE routine, which unlinks the device and returns the status as the OPEN-routine does.

- Further needed is a GETBYTE routine, which receives the data from your device and returns the data in the A-register and the status in the Y-register. If your device is a write only device (such as a printer) you have to return with errorcode 146 (not implemented function) in the Y-register.

- A PUTBYTE routine, sends a byte (which will be in the A-register) to your device, and returns, as the other routines do, the status. If your device is read only, then return the 146 errorcode.

- A GET STATUS routine stores the status of your device (max. 4 bytes) at DVSTAT ($02EA. D). If the GET STATUS function is not necessary, you have to leave the dummy routine with 146 in your Y-register (error).

- A SPECIAL COMMAND routine is required, if you need more commands than previous. If not, return with Y=146.

OS will load the X-register with the IOCB number times 16 so you are able to get specific file information out of the user IOCB.

These 6 entries have to be placed in a so called handlertable. The vectors of these have to be one less than the real address, due to OS requirements.

```
+----------------+
¶ OPEN vector-1  ¶
+----------------+
¶ CLOSE vector-1 ¶
+----------------+
¶GETBYTE vector-1¶
+----------------+
¶PUTBYTE vector-1¶
+----------------+
¶GETSTAT vector-1¶
+----------------+
¶SPECIAL vector-1¶
+----------------+
```

Now you have to add the device to the device table. A device entry needs 3 bytes. The device name, which is usually a character that indicates the device (first character of the full devicename) is first. Second, a vector that points to the devicehandler.

```
+-----------------+
¶  device name    ¶
+-----------------+
¶ handler table   ¶
+-               -+
¶     address     ¶
+-----------------+
```

If you only want to change the handler of a device to your own handler, you only have to scan the devicetable (started from $031A) and let the vector point to your handler table.
If it is a totally new device, you have to add it, at the next free position of the device table (filled with zero).
The first listing shows you a handler for a new printer device. Calling INITHAN will install the new handler table. Now you can connect a printer with centronics interface at gameport 3 & 4 (see connection scheme). After each SYSTEM RESET you have to initialize the device again. For program description see program listing.
The second listing is a listing of an inexpensive (write only) RS232 interface for your ATARI. Just call INITHAN and the new device will be added to the device table. It is now possible to use it like any other device. The RS232 output is on gameport 3 (see connection scheme). It is not our intention to describe detail the working of the RS232 interface. The comments in the program should help a bit though.

A BOOTABLE TAPE GENERATOR PROGRAM

CHAPTER 8

The following program allows you to generate a bootable program on tape. This generator must be in memory at the same time as the program.
After you have jumped to the generator, a dialogue will be started. First, the boot generator asks for the address where your program is stored (physical address). After you have entered start- and end-address (physical), you will be asked to enter the address where the program has to be stored during boot (logical address). The generator further asks for the restart address (where OS must jump to, to start your program).
There is no feature to define your own initialization address. This address will be generated automatically and points to a single RTS.
Also given is the boot continuation code, which will stop the cassette motor, and store the restart address into DOSVEC ($0A. B).
So, you just have to put a cassette in your recorder, start the generator, and the dialogue will be started.
The generator puts the boot information header in front of your program, so there have to be at least 31 free bytes in front of the start address (physical & logical).

The generator program will not be explained here, but after reading the previous chapters you should have the knowledge to understand it. There are also some helpfull comments in the program.

A DIRECT CASSETTE TO DISK COPY PROGRAM

CHAPTER 9

If you have a bootable program on cassette, and you want to have it on a bootable disk, the following program will help you.
This program is easy to understand if you have read the previous chapters. It allows you to copy direct from tape to disk, using a buffer.
When you start your program from your machine language monitor, you must put the cassette into the recorder and the formatted disk into the drive (#1). After the beep, press return, and the cassette will be read. After a succesful read the program will be written on the disk. If, during one of these IO's an error occurrs, the program stops and shows you the error code.
Now, power up the ATARI again and the disk will be booted. Sometimes the program doesn't work correctly. Just press SYSTEM RESET and most of the time the program will work.
The copy program will not be described, but it has helpful comments, and you possess the knowledge of the IO.
It is important that the buffer (BUFADR) is large enough for the program.

```

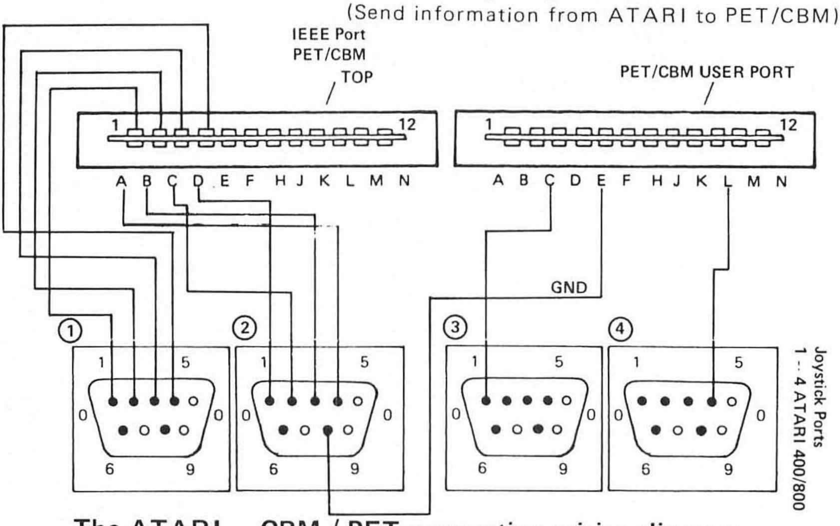
HOW TO CONNECT YOUR ATARI WITH ANOTHER COMPUTER

CHAPTER 10

The following programs make it possible to communicate between an ATARI and a PET/CBM. The output ports are referenced as PORTA and DATABUS between the two computers. Bit 0 on the ATARI PORTB is the 'hand' of the ATARI and bit 7 on the same port is the 'hand' of the CBM. Now a handshake communication between both can be started. The routines PUT and GET are, in this case, dummies. Further, you need a stop criterium to stop the transfer. See these routines merely as a general outlines and not as complete transfer programs.



The ATARI -- CBM / PET connection-wiring diagram

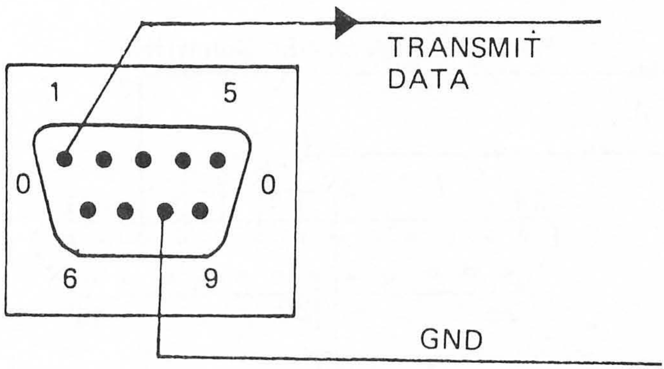
300 BAUD SERIAL INTERFACE VIA THE ATARI JOYSTICK PORTS

Chapter 11

The following construction article allows you to build your own RS232 interface for the ATARI computer. The interface only works with 300 Baud and just in one direction (output).

The interface consists of:

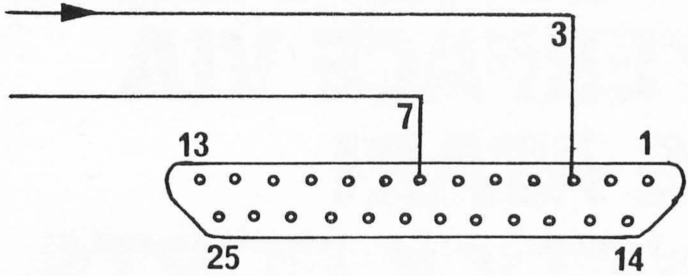
a) RS232 serial interface driver on a bootable cassette or as a SYS file on disk.
b) Two wires hooked up to game port 3 on your ATARI.



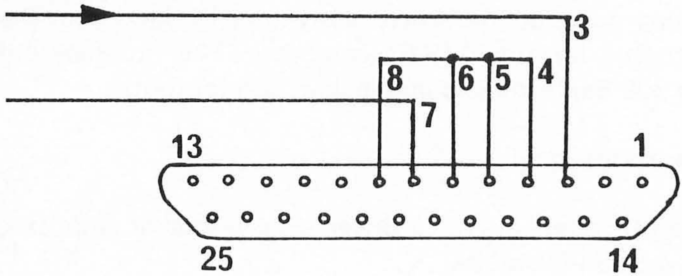
GAME PORT 3

We used this interface with a DEC-writer, a NEC spinwriter, and a Brother HR-15. The DEC-writer worked with just the two wires connected (Transmit DATA and GND).
The Spinwriter and the Brother needed some jumper wires as shown below:

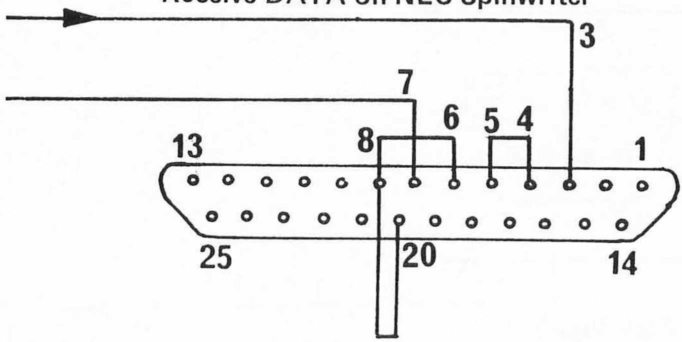
Receive data on DEC-writer



Receive data on Brother HR-15



Receive DATA on NEC Spinwriter



Depending on the printer you use you will have to make the appropriate wiring according to the instructions in the manual.

The source code for the RS232 driver is listed on a previous page in this book.

This is a sample printout in BASIC:

```
10 OPEN #1,8,0,"R:"
20 FOR X=1 TO 10
30 PRINT #1,"ELCOMP-RS232",X
40 NEXT X
50 CLOSE #1
```

will generate the following printout:

```
ELCOMP-RS232        1
ELCOMP-RS232        2
ELCOMP-RS232        3
ELCOMP-RS232        4
ELCOMP-RS232        5
ELCOMP-RS232        6
ELCOMP-RS232        7
ELCOMP-RS232        8
ELCOMP-RS232        9
ELCOMP-RS232        10
```

The source code for the RS-232 Interface you will find on page 72.

Printer Interface

Chapter 12

Screen to Printer Interface for the ATARI 400/800

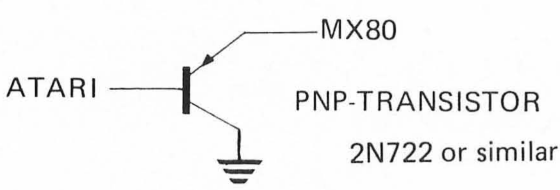
Many ATARI users would like to connect a parallel interface to the computer. For many people buying an interface is too expensive. On the other hand, they may not have the experience to build one by their own. Also a lot of software is needed.

The following instructions make it easy to hook up an EPSON or Centronics printer to the ATARI.
Only seven of the eight DATA bits are used for a printout.
DATA 8 is grounded. BUSY and STROBE are used for handshake. There is an automatic formfeed every 66 lines. Thus it is necessary to adjust the paper before starting to print. You may need to make several trials to find the best position of the paper. For a different form-length you may POKE 1768, ... (number of lines). After system reset the line counter is set to zero, so you have to provide your own formfeed for a correct paper position.

You can control the length of a line by a POKE 1770, xxx. After doing so, press system reset and enter LPRINT.

The program SCREENPRINT is called by BASIC thru an USR (1670) and by the assembler with a GOTO $0687.

You may install pnp transistors between the game output and the printer, as it is shown in this little figure and in the schematic on page 112.



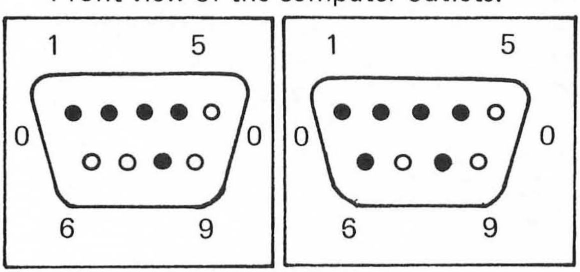
The next figure shows the connection of the ATARI game outlets and the connector for the MX-80 printer. This is a so-called Centronics interface and the program can be used with each printer and this interface.

EPSON MX80 – ATARI 400/800
Interconnection-Scheme

MX80-Connector	ATARI-Connectors Port3	Port 4
Pin#	Pin#	Pin#
1 (19) $\overline{\text{STROBE}}$		4
2 (20) DATA 1	1	
3 (21) DATA 2	2	
4 (22) DATA 3	3	
5 (23) DATA 4	4	
6 (24) DATA 5		1
7 (25) DATA 6		2
8 (26) DATA 7		3
9 (27) DATA 8		8
11 (29) BUSY		6
(GND)	8	8

(19)–(29) = Ground (GND)

Plugs seen from the rear view.
Front view of the computer outlets. [1]



PORT 3 PORT 4

The next figure shows the program.

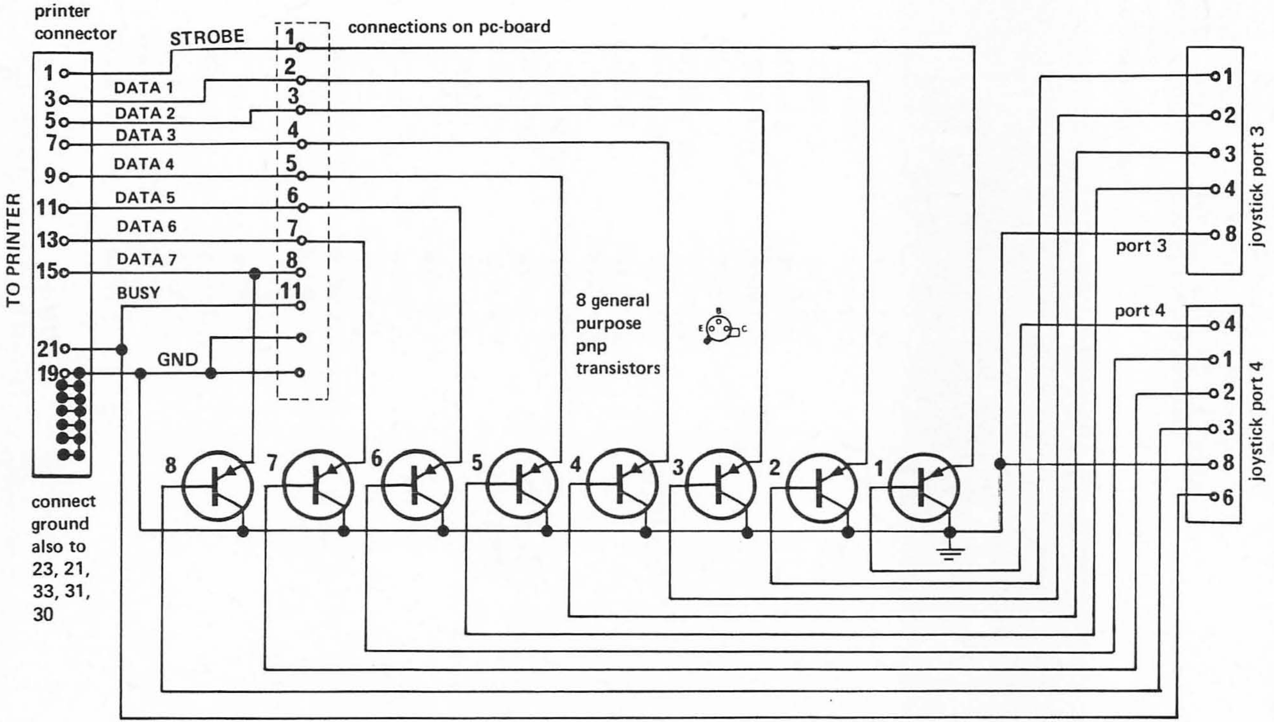
Program description:

Address	
0600 – 06IE	end of the booting part
0610 – 062B	HANTAB for the ATARI OS
062C – 0642	opens the ports for output
0643 – 066D	printer driver
066E – 0685	initialize. Now LPRINT and PRINT "P" use the printer driver
0686 – 06BD	label BASIC starting address for a call by BASIC Label NORMAL starting address for a call by assembler.



Schematic of the parallel printer interface for the EPSON MX-80 or MX100. (Centronics like)

The numbers on the printer connector may vary with the different parallel printer used.
In this case go by the name of signal rather than by the numbers.

06BE – 06D0	Copyright notice
06DL – 06E5	Subroutine, brings one ASCII character from the accumulator to the printer
06E6 – 06EA	values for the various counters ROW sets the number of horizontal lines to 23. COLUMN sets the number of characters of one line to 39. COUNT sets the number of lines between two formfeeds to 65 LCOUNT, LINLEN contains the actual parameters for the number of characters and lines.

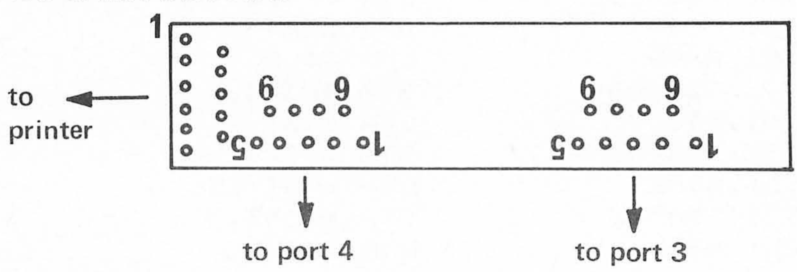
If you want to use this program, it has to be bootable. Therefore you must enter both programs and start the boot routine at address $ 6000. This will create a bootable cassette, you can use afterwards in the following manner, to enter the SCREENPRINT in your computer.

- turn off the computer
- press the start key
- turn on the computer
- release the start key
- press PLAY on the recorder and
- press RETURN

BASIC or assembler-editor cartridge must be in the left slot of your ATARI computer.

How to wire the board:



Differences between the ATARI Editor/Assembler Cartrigde and ATAS-1 and ATMAS-1

The programs in this book are developed using the ATMAS (ATAS) syntax. In the following I would like to explain the difference of some mnemonics of the ATARI Editor/Assembler cartridge and the Editor/Assembler and ATMAS-1 from Elcomp Publishing.
Instead of the asterisk the ATAS uses the pseudo op-codes ORG.
Another difference is that the ATAS is screen oriented (no line numbers needed). Instead of the equal sign ATAS uses EQU.
Additionally ATAS allows you the pseudo op-codes EPZ: Equal Page Zero.
There is also a difference in using the mnemonics regarding storage of strings within the program.

ATARI		ELCOMP	
– BYTE "STRING"	=	ASC "STRING"	
– BYTE $	=	DFB $	(Insertion of a byte)
– WORD	=	DFW	(Insertion of a word Lower byte, higher byte)

The end of string marker of the ATARI 800/400 output routine is hex 9B.
In the listing you can see, how this command is used in the two assemblers:

ATARI Assembler:	–.BYTE $9B
ATMAS from ELCOMP	– DFB $9B

Depending on what Editor/Assembler from ELCOMP you use, the stringoutput is handled as follows:

1. ATAS 32K and ATAS 48K cassette version

```
   LDX # TEXT
   LDY # TEXT/256
TEXT ASC "STRING"
    DFB$9B
```

2. ATMAS 48K

```
   LDX # TEXT:L
   LDY # TEXT:H
TEXT ASC "STRING"
    DFB $9B
```

There is also a difference between other assemblers and the ATAS-1 or ATMAS-1 in the mnemonic code for shift and relocate commands for the accumulator.

(ASL A = ASL) = 0A
(LSR A = LSR) = 4A
ROL A = ROL = 2A
ROR A = ROR = 6A

The ATMAS/ATAS also allows you to comment consecutive bytes as follows:

JUMP EQU $F5.7

$F5 = Label Jump
$F6 and $F7 are empty locations.
This is a comment and not an instruction.
